Abstract

This paper presents the results of a European benchmark on multiscale creep modeling for cementitious materials, performed in the framework of the COST Action TU1404 "Towards the next generation of standards for service life of cement-based materials and structures". Three micromechanical models from three research groups have been adopted for modeling the basic non-aging creep of cementitious materials. The benchmark is based on the hypothesis that creep results only from calcium-silicate-hydrates (C-S-H) and that viscoelastic behavior of all microstructural constituents are maturity- and composition-independent. By comparing model results among themselves as well as by comparing model predictions with experimental results obtained from three different laboratories, we demonstrate that creep upscaling from micrometer-sized C-S-H to centimeter-sized macroscopic samples of cement paste, mortar, and concrete, and from minutes-long creep tests at early ages to days-long creep tests at very mature ages is indeed possible. The benchmark also highlights the importance of considering micro-anisotropy of C-S-H in terms of non-spherical shapes for C-S-H hydrates.

Keywords: cement paste, mortar, concrete, viscoelasticity, micromechanics, Calcium-Silicate-Hydrate (C-S-H), experiments, basic creep, early-age

1. Introduction

Herein, a benchmark regarding multiscale modeling of creep of cementitious materials is presented. It was initiated within the framework of the COST Action TU1404 "Towards the next generation of standards for service life of cement-based materials and structures" [1]. The benchmark refers to nonaging creep properties of cement paste, mortars, and concretes, both at early and mature material ages. Innovative creep tests performed at three laboratories on seven different mixes constitute the experimental basis for the benchmark. This study complements the multiscale modeling benchmark focused on the early-age evolution of the stiffness and strength of cementitious materials [2].

Multiscale micromechanics models for homogenization of mechanical properties of cementitious materials [3, 4, 5, 6, 7, 8, 9] are applied for predicting the creep properties of young and mature cementitious materials. These models are adopted by the three participating research groups and applied to quantify the evolution of the non-aging creep behavior of cement paste, mortar, and concrete—from very early to very mature ages. Recently, it was shown that the hydration products, which form during the physico-chemical processes of cement hydration, exhibit intrinsic creep properties at the micrometer scale [10], irrespective of maturity or composition of the material. Following this hypothesis, the creep behavior of the hydrates will be characterized by downscaling minutes-long creep tests performed on young cement paste. The such-obtained *intrinsic* hydrate creep function is thereafter used for bridging length and time scales. In more detail, we first aim for predicting creep properties at larger mate-

rial scales, i.e. at the mortar and concrete scales. Moreover, we aim for predicting creep properties at larger time scales, i.e. for very mature materials (with ages up to several years) and/or loading durations of several days. The required experimental data are obtained from three different concrete laboratories and include novel creep test results stemming from the experimental stage of the COST Action TU1404 [1].

The article is structured as follows: Section 2 refers to the experimental data. Section 3 is devoted to a brief description of three complementary multiscale modeling approaches. Section 4 refers to the actual benchmark. At first, the strategy is described. Thereafter, a top-down identification approach is used to quantify the creep constants of the viscoelastic hydrates, based on the results of three-minutes creep tests of hydrating cement pastes. After that, all three models are used to predict the short-term creep behavior of hydrating mortars and concretes, as well as the longer-term creep behavior of a very mature cement paste. In Section 6, the paper is closed with conclusions obtained from the comparison of the three independent creep models and their performance.

2. Experimental data

The experimental data included in the benchmark were obtained from hourly-repeated minutes-long creep tests on six different hydrating cementitious materials, including one concrete representative of nuclear containment buildings, as well as from one 30-days-long creep test of a very mature cement paste, see also Table 1. Direct uniaxial compression experiments were performed. Every single test was organized in two phases: the application of the loading, referred to as the initial loading ramp, and the actual creep tests during which the loading was kept constant, referred to as the load plateau. Load cells measured the applied compressive forces F, as a function of time t. Dividing $F(t)$ by the cross-sectional area A_c of the tested specimen, delivers the time-evolution of the prescribed compressive normal stress

$$\sigma(t) = \frac{F(t)}{A_c} \,. \qquad (1)$$

The resulting deformation of the specimens, i.e. the time-evolution of the compressive normal strain, $\varepsilon^{\exp}(t)$, was measured with a suitable equipment.

All creep tests of the benchmark refer to a practically constant microstructure of the tested material. This is the rationale for the expression "nonaging" creep tests. In addition, the imposed compressive loading was always smaller than 20% of the compressive strength of the material at the time of testing. Thus, the specimens remained virtually undamaged and testing was carried out in the linear creep regime [14]. Notably, given the short repeated creep tests with strains $\varepsilon^{\exp}(t)$ refer to basic creep strains, because isothermal testing was performed (no thermal strains), the specimens were sealed (no drying shrinkage nor drying creep), and the microstructure was virtually constant during testing (no autogeneous shrinkage).

Repeated minutes-long basic creep tests are well-suited for efficiently characterizing the hardening-induced evolution of nonaging creep properties [11, 12, 15, 16, 17, 18]. During minutes-long loading, the microstructure of the material remains virtually the same, because the chemical reaction between cement and water does not proceed significantly. The ultra-short creep tests are repeated hourly while the specimen remains installed in the loading apparatus. Basic creep strains during repeated ultra-short creep tests are shown to be reversible [11, 16, 18]. Irreversible strains, as observed in long-term creep tests during the maturation, are absent, see e.g. Fig. 18 of Ref. [11]. Moreover, results from *repeated* creep tests with minutes-long loading periods alternating with periods of virtually no loading for almost one hour are shown to be very similar to results from *single* creep tests on previously unloaded samples at the corresponding age [16, 18].

The benchmark is particularly focused on creep strains $\varepsilon_v^{\exp}(t)$. Creep strains can be obtained from the measured total strains $\varepsilon^{\exp}(t)$ by subtracting the elastic strains $\varepsilon_{el}^{\exp}(t)$:

$$\varepsilon_v^{\exp}(t) = \varepsilon^{\exp}(t) - \varepsilon_{el}^{\exp}(t) \,. \qquad (2)$$

The elastic strains, in turn, can be quantified based on knowledge regarding the applied uniaxial stresses $\sigma(t)$, see Eq. (1), and the modulus of elasticity E, following Hooke's law:

$$\varepsilon_{el}^{\exp}(t) = \frac{\sigma(t)}{E} \,. \qquad (3)$$

Eqs. (2) and (3) underscore that accurate quantification of the modulus of elasticity is of considerable importance for the accurate quantification of creep strains, in particular since elastic deformations typically outweigh the viscous ones by one order of magnitude.

2.1. Creep tests performed at Vienna University of Technology (TUW)

The benchmark involves experimental data from five early-age testing campaigns carried out at TUW (Table 1). The tested materials were produced with an ordinary Portland cement of type CEM I 42.5 N, distilled

Table 1: Initial compositions of the analyzed cementitious materials, testing ages, and durations of the creep tests; w/c, s/c, and a/c refer to the initial water-to-cement, sand-to-cement, and aggregate-to-cement mass ratios

water, and quartz sand/aggregates. Mixes 1, 2, and 3 refer to cement pastes with initial water-to-cement mass ratios w/c amounting to 0.42, 0.45, and 0.50, respectively. The experimental data are taken from [11]. Mix 4 refers to a laboratory mortar, produced with $w/c = 0.50$ and initial sand-to-cement mass ratio s/c amounting to 3.0. Mix 5 refers to a laboratory concrete, produced with $w/c = 0.50$ and initial aggregate-to-cement mass ratio a/c amounting to 3.0. Notably, sand and aggregates were oven-dried. The experimental data are taken from [12]. A degree of hydration was assigned to every three-minutes creep test, based on quasi-isothermal differential calorimetry measured for all three cement paste mixes, and considered equal for the corresponding mortar and concrete mixes with similar w/c ratio [11].

As regards test evaluation, the unloading modulus was used as a first estimate of the modulus of elasticity. This allowed for extracting the creep strains from the measured total strains, see Eqs. (1)–(3) and [11, 12]. The obtained creep strains were unrealistic, because unphysical *tensile* creep strains developed right after the beginning of the loading phase, a phenomenon labelled "tensile undershooting", see Fig. 7 (a) in [11]. In other words, the elastic strains evaluated based on the unloading modulus were larger (in absolute numbers) than the measured total strains right after the start of the loading. Thus, the estimate of the modulus of elasticity was gradually increased, resulting in gradually decreasing (absolute values of) elastic strains, until the tensile creep strains had disappeared entirely. The obtained final es-

timate of the modulus of elasticity was (i) typically by 2-5% larger than the unloading modulus, and (ii) practically equal to the modulus of elasticity quantified based on ultrasonic pulse velocity measurements of longitudinal and shear waves [11].

2.2. Creep tests performed at Université libre de Bruxelles (ULB)

Five-minute-long basic creep tests were carried out at early material ages at ULB, in order to characterize the "VeRCoRs"[1] concrete within the framework of the COST Action TU1404, see Mix 6 in Table 1. The corresponding test data are original contributions of this paper. Therefore, they are described in more detail.

Concrete was produced using CEM I 52.5 N CE CP2 NF. It consisted of 96% (weight) ordinary Portland cement and 4% limestone filler. The cement consisted of 68, 10, 9, 7, 2.2, and 3.3% (weight) of C_3S, C_2S, C_3A, C_4AF, MgO, and Gypsum, respectively. Oven-dried siliceous sand from Sandrancourt in France and water-saturated siliceous-calcareous gravel in size classes 4/11 mm and 8/16 mm were used. Superplasticizer SIKAPLAST techno 80 was added to the mixing water. As for the production of $1\,m^3$ of concrete, the

---

[1]"VeRCoRs", acronym of "Verification Réaliste du COnfinement des RéacteurS", is a 1/3 scale mock-up [19] of a nuclear power plant containment building, built at EDF lab, to improve both knowledge on and modeling of containment buildings ageing. The structure is heavily instrumented [20] and its concrete is the subject of many studies, see for example [21] regarding creep.

following mix proportions were used: 320 kg of binder, 830 kg of dry sand, 995 kg of water-saturated aggregates, 2.4 kg superplasticizer, and 171 kg of extra water, see also [17].

The evolution of the degree of hydration ξ was quantified based on isothermal calorimetry tests, performed inside a 8-channel TAM Air micro-calorimeter at 20°C. The tests delivered the cumulatively released heat per unit mass of the binder, $Q(t)$, see Fig. 1. Accounting for

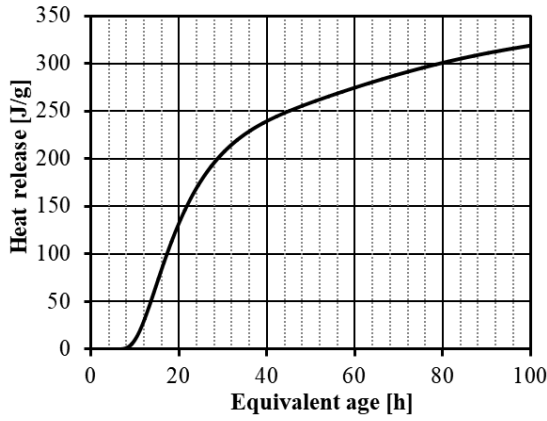

Figure 1: Calorimetry-based cumulative heat release Q for VeRCoRs concrete (Mix 6) as function of the age of the material

a ultimate heat of the binder amounting to 510 J/g, see Neville [22] for the enthalpies of the individual clinker phases, the degree of hydration ξ is quantified as

$$\xi(t) = \frac{Q(t)}{510\,\text{J/g}} \,. \qquad (4)$$

Uncertainties of ξ regarding the determination of the ultimate heat and the calorimetry measurements remained unconsidered. As for mechanical testing, a cylindrical specimen with a diameter of 97 mm and a height of 550 mm was produced. After casting, the specimen was sealed and placed in an air-conditioned chamber at 20°C and a relative humidity of 90%. The setting process was monitored based on ultrasonic longitudinal and shear waves which were sent through the specimen [23]. Shortly after the final setting, 12.1 h after production, the sample was demolded, ground on both circular end faces, and sealed by means two self-adhesive aluminum sheets.

The tests were carried out in a Walter+Bay LFMZ 100 kN electromechanical testing machine, located in an room conditioned to a temperature of 20°C and a relative humidity of 50%. The length-changes of the specimen were measured in its central part, which is virtually free of undesired shear stresses resulting from friction in the interface between the load platens and the specimen, see Fig. 2 of [24]. To this end, two metal rings were fixed to the specimen, using three anchorages with elastic blades per ring [25]. The initial distance between the rings was equal to 350 mm. Three displacement sensors of type Solartron, with a maximum stroke of 0.5 mm, were equally distributed around the specimen. They measured the changes of distance between the two metal rings. The three measured length changes, $\Delta\ell_i$ with $i = 1, 2, 3$, were averaged and divided by the measurement length, in order to quantify the total axial strain of the specimen

$$\varepsilon^{\text{exp}}(t) = \frac{1}{350\,\text{mm}} \sum_{i=1}^{3} \frac{\Delta\ell_i(t)}{3} \,. \qquad (5)$$

Hourly-repeated five-minute creep testing was started at a concrete age of 14 h. The maximum loading was equal to 20% of the age-specific compressive strength. As for the initial loading ramp, the desired loading was applied within 10 seconds, in a force-controlled fashion. The loading rate of the first test amounted to $\dot\sigma = 0.09$ MPa/s. Due to material hardening, it increased from test to test. The loading rate of the last test for which heat release measurements are available, carried out 94 h after production, was equal to $\dot\sigma = 1.02$ MPa/s. Once the desired load level was reached, the force was kept constant for 5 min. Subsequently, the specimens were unloaded within 10 seconds. In order to maintain contact between the load platens and the specimen, a small permanent stress amounting to 0.041 MPa was imposed on the sample between two successive tests. Full details on the test protocol can be found in Delsaute and Staquet [18].

As regards test evaluation, measured total strains $\varepsilon^{\text{exp}}(t)$ are decomposed into elastic and viscous strains according to (2). The elastic modulus was estimated from the slope of the central 60% of the stress-strain diagram within the loading and unloading branches, respectively, [26, 27]. The average of both loading and unloading modulus for a specific creep test is considered as estimate of the elastic modulus. Notably, loading and unloading moduli are almost identical, and the evolution of the moduli is in agreement with results obtained by the laboratory of Électricité de France (EDF), 28 days after production [17], see Fig. 2. The material's actual *elastic* modulus E is most likely a few percent larger than the loading/unloading modulus due to short-term creep strains occurring during loading/unloading [11]. Elastic strains following from (3), evaluated for the loading/unloading moduli, thus very likely overestimate the real elastic strains such that the viscous strains

4

according to Eq. (2) might be significantly underestimated.

Figure 2: Evolution of loading and unloading moduli of VeRCoRs concrete (Mix 6), determined from hourly-repeated 5-min creep testing at early ages, and 28-days-stiffness values determined by EDF [17]

As for a condensed representation of the experimental data, the resulting viscous creep strains $\varepsilon_v^{\text{exp}}(t)$ are represented by means of the viscous creep function J_v^{exp} as

$$\varepsilon_v^{\text{exp}}(t) = \int_{-\infty}^{t} J_v^{\text{exp}}(t - \tau)\,\dot{\sigma}(\tau)\,\mathrm{d}\tau, \qquad (6)$$

with logarithmic viscous creep function J_v^{exp} reading as [28]

$$J_v^{\text{exp}}(t - \tau) = \frac{A}{E}\ln\left[1 + (\mathrm{e} - 1)\left(\frac{t - \tau}{t_c}\right)^K\right]. \qquad (7)$$

In Eq. (7), parameter A is the amplitude of the creep coefficient after 5 minutes of loading and parameter K is related to the kinetics of the basic creep, and $t_c = 5$ min is the reference time. The amplitude parameter A significantly decreases from 0.24 at the first creep test at an age of 14 h to 0.05 for the last creep test at an age of 318 h, while the kinetic parameter decreases from a value of 0.5 at early age to 0.4 at mature ages, see Fig. 3.

2.3. Creep test performed at the Canadian National Research Council (NRC)

Tamtsia and Beaudoin [13] performed a 30-days creep test of a cement paste with $w/c = 0.5$, which was stored for 30-years under water, see Mix 7 in Table 1. Although the characterized material was still not perfectly inert, the reaction kinetics between cement and water had decayed so significantly, that the microstructure of the material was in good approximation constant throughout the test. Thus, also this test refers to nonaging creep properties.

The degree of hydration of the material is estimated as follows. Using $w/c = 0.50$ and the initial Blaine fineness of $340\,\text{m}^2/\text{kg}$ [29] as input, the empirical law by Lin and Meyer [30] suggests that the final degree of hydration amounts to 87%.

Figure 3: Evolution of the creep parameters A and K for VeRCoRs concrete (Mix 6), determined from hourly-repeated 5-min creep testing at early ages

3. Multiscale models

Three different multiscale models participate in the benchmark. They are based on methods of continuum micromechanics [31]. The models account for two key features of the three-dimensional microstructure of cementitious materials:

Material organogram: Each model is based on a specific representation of the hierarchical organization of cementitious materials, see Fig. 4. The models introduce three to five different scales of observations. They range from the macroscale of concrete down to microscopic and/or nanoscopic scales of hydration products and pores.

Number and type of material constituents: At each scale of observation, the microstructures are envisaged to consist of a specific number of quasi-homogeneous constituents. They are referred to as "material phases".

All three models account for four key features of the material phases. Two of them are of qualitative nature, the other two are of quantitative nature.

5

Phase shape and orientation: Each material phase is modeled based on an ellipsoidal shape and non-preferred orientation. In more detail, the involved approaches include spherical phases, where orientation does not matter, as well as prolate (needle-like) or oblate (lens-like) spheroidal phases which are modeled to be isotropically oriented in space.

Phase arrangement and interaction: If the material phases, forming the microstructure at a specific scale of observation, exhibit direct mutual interaction, the self-consistent scheme will be used for homogenization [32, 33]. If the material phases form a matrix-inclusion composite, Mori-Tanaka-Benveniste scheme will be used for homogenization [34, 35]. If coated spheres are envisaged, creep homogenization is performed according to Ref. [36].

Hydration-induced evolution of phase volumes: The early-age evolution of macroscopic viscoelastic properties of cementitious materials is explained based on evolving volume fractions. The models account for the consumption of cement and water and the associated production of hydrates.

Material constants: All material phases are considered to be isotropic. Their material behavior is either modeled as being linear elastic or linear-viscoelastic. Material constants are assigned to the smallest quasi-homogeneous constituents, rather than material parameters.

As for the linear-elastic material phases (index p), generalized Hooke's law describes the relation between average phase stresses σ_p and average phase strains ε_p:

$$\sigma_p(t) = \mathbb{C}_p : \varepsilon_p(t) \,. \tag{8}$$

The time-independent isotropic elastic stiffness tensors $\mathbb{C}_p$ read as

$$\mathbb{C}_p = 3\,k_p\,\mathbb{I}_{vol} + 2\,\mu_i\,\mathbb{I}_{dev} \,, \tag{9}$$

where k_p and μ_p stand for the bulk and the shear moduli of phase p, and $\mathbb{I}_{vol}$ and $\mathbb{I}_{dev}$ for the volumetric and deviatoric parts of the symmetric fourth-order identity tensor.

As for the viscoelastic hydrate phases (index h), the average stresses σ_h are related to the average strains ε_h based on the following convolution integral, expressing Boltzmann's superposition principle [38]:

$$\varepsilon_h(t) = \int_{-\infty}^{t} \mathbb{J}_h(t-\tau) : \dot{\sigma}_h(\tau)\,\mathrm{d}\tau \,. \tag{10}$$

The time-dependent creep tensor functions $\mathbb{J}_h(t-\tau)$ are isotropic. They contain a time-independent elastic part $\mathbb{C}_h^{-1}$ and a time-dependent viscous part $\mathbb{J}_{v,h}(t-\tau)$:

$$\mathbb{J}_h(t-\tau) = \mathbb{C}_h^{-1} + \mathbb{J}_{v,h}(t-\tau) \,. \tag{11}$$

The three models participating in the benchmark are based on a deviatoric tensorial creep tensor function, reading as

$$\mathbb{J}_{v,h}(t-\tau) = \frac{\mathbb{I}_{dev}}{2\,\mu_{c,h}} \left(\frac{t-\tau}{t_{ref}}\right)^{\beta_h} \,, \tag{12}$$

whereby $t_{ref} = 1\mathrm{d} = 86400\mathrm{s}$ denotes the constant reference time. The two material constants $\mu_{c,h}$ and β_h stand for the shear creep modulus $\mu_{c,h}$ and the power-law creep exponent β_h.

3.1. Model 3N

The multiscale Model 3N is based on a 3-scale representation of concrete and on needle-shaped hydrates, hence the acronym "3N". This representation was introduced in [5] in the context of upscaling stiffness and strength of hydrating cement pastes, and it was applied to creep homogenization in [7]. According to Model 3N, the microstructure of concrete and mortar consists of a matrix made of cement paste and spherical inclusions representing sand and aggregates. The microstructure of cement paste consists of a matrix referred to as "hydrate foam" and spherical inclusions representing clinker grains. The microstructure of the hydrate foam consists of a polycrystalline arrangement of spherical capillary porosity and hydrate-gel needles which are isotropically oriented in space. For the sake of simplicity, the aspect ratio of the needles is set equal to infinity [5]. The microstructure of the hydrate-gel needles is not resolved explicitly, but it would contain nanoscopic solid hydrates and gel pores.

The hydration-induced evolution of the volume fractions of clinker, hydrates, and pores is quantified based on Powers' model [39]. The latter expresses the volume fractions as a function of the degree of hydration ξ and the water-to-cement ratio w/c. Accordingly, the cement paste-related phase volume fractions of clinker f_{clin}^{cp}, of water $f_{H_2O}^{cp}$, of hydrates f_{hyd}^{cp}, and of self-desiccation-
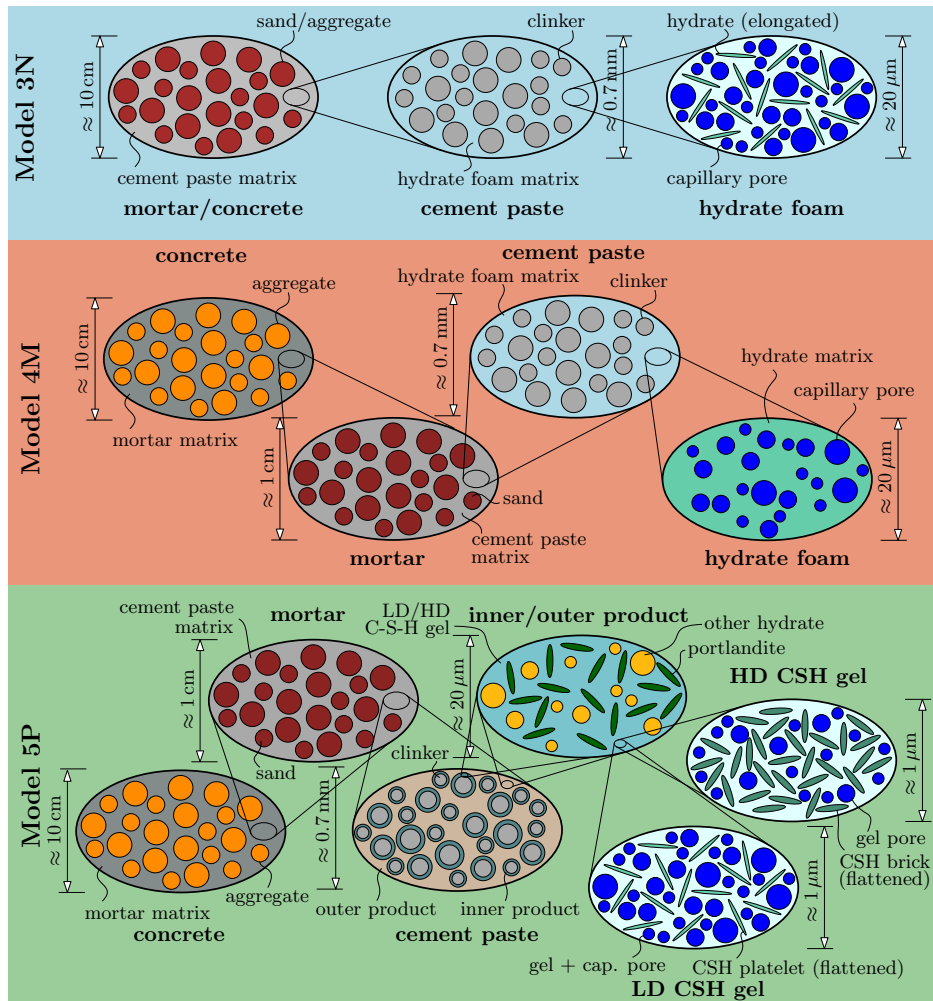

6

Figure 4: Material organograms representing the envisaged hierarchical organization of concrete: (a) Model 3N: 3-scale representation including needle-shaped hydrates after Pichler and Hellmich [5], Königsberger et al. [7]; (b) Model 4M: simplified 4-scale representation including a hydrate matrix after Honorio et al. [6]; (c) Model 5P: 5-scale representation including platelet-shaped hydrates, multi-hydrate extension of Sanahuja et al. [3, 37]; the two-dimensional sketches illustrate qualitative properties of three-dimensional representative volume elements

induced air porosity f_{air}^{cp} read as [5]:

$$f_{clin}^{cp} = \frac{20\,(1 - \xi)}{20 + 63\,w/c} \geq 0\,,$$

$$f_{H_2O}^{cp} = \frac{63\,(w/c - 0.42\,\xi)}{20 + 63\,w/c} \geq 0\,,$$

$$f_{hyd}^{cp} = \frac{43.15\,\xi}{20 + 63\,w/c}\,,$$

$$f_{air}^{cp} = \frac{3.31\,\xi}{20 + 63\,w/c}\,. \qquad (13)$$

Elastic phase properties of all phases are given in Table 2. Only the hydrate phase is considered to be viscoelastic, with viscous creep tensor function according to Eq. (12).

Table 2: Isotropic elastic phase properties: $k_i \mid \mu_i$ in GPa

Phase	Model 3N	Model 4M	Model 5P
Hydrates	18.7 | 11.8	18.7 | 8.5	-
C-S-H	-	-	25.2 | 15.9
Portlandite	-	-	35.6 | 15.0
Other Hyd.	-	-	33.3 | 15.4
Pores	0 | 0	0 | 0	0 | 0
Clinker	117 | 53.8	113 | 51.9	113 | 51.9
Sand	37.8 | 44.3	36.1 | 27.1	36.1 | 27.1
Aggregates	37.8 | 44.3	36.1 | 27.1	36.1 | 27.1

Creep homogenization is based on the correspondence principle. The time-dependent problem is transformed to the Laplace-Carson space, see [10] for computational details. There, the upscaling challenge represents itself as a sequence of quasi-elastic homogenization problems. The pointwisely-computed solution is finally back-transformed to the regular time space.

3.2. Model 4M

The multiscale Model 4M is based on a 4-scale representation of concrete with a hydrate matrix, hence the acronym "4M". This representation has been used to upscale thermal [40] and electromagnetic [41, 42] properties of cement-based materials and is a simplified version of the modeling approach presented in Ref. [6]. According to Model 4M, the microstructure of concrete consists of a matrix made of mortar and spherical inclusions representing aggregates. The microstructure of mortar consists of a matrix made of cement paste and spherical inclusions representing sand. The microstructure of cement paste consists of a hydrate-foam matrix and spherical inclusions representing clinker grains.

The microstructure of the hydrate foam consists of a hydrate matrix and spherical inclusions representing capillary pores. The microstructure of the hydrate matrix is not resolved explicitly, but it would contain nanoscopic solid hydrates and gel pores.

By analogy to Model 3N, the hydration-induced evolution of the volume fractions of clinker, hydrates, and pores is quantified based on Powers' model [39]. Elastic phase properties of clinker, sand, and aggregates are given in Table 2. The intrinsic hydrate stiffness is back-identified from the measured Young's modulus evolutions of Mix 1-3. The creep tensor function of the hydrate matrix is considered to be deviatoric, see Eq. (12).

Creep homogenization is performed using Mori-Tanaka estimates extended to aging linear viscoelasticity [43], using a correspondence principle based on Volterra integral operators. The solution is made in time space using numerical integration of Volterra operators.

3.3. Model 5P

The multiscale Model 5P is based on a 5-scale representation of concrete and on platelet-shaped hydrates, hence the acronym "5P". This representation is a multi-hydrate extension of the modeling approach presented in [3]. According to Model 5P, the microstructure of concrete consists of a matrix made of mortar and spherical inclusions representing aggregates. The microstructure of mortar consists of a matrix made of cement paste and spherical inclusions representing sand. The microstructure of cement paste consists of a matrix made of "outer products" and spherical inclusions representing clinker grains covered by "inner products". The microstructure of inner/outer products consists of a matrix made of high-density/low-density C-S-H-gel, oblate portlandite inclusions (with an aspect ratio amounting to 0.1), and spherical inclusions representing other hydrates such as AFm, AFt, Calcium Aluminate, Hydrogarnet, etc. The microstructure of the two types of C-S-H gels consists of a polycrystalline arrangement of spherical pores and oblate solid hydrates which are isotropically oriented in space. The low-density C-S-H gel consists of gel pores, capillary pores, and solid C-S-H platelets with an aspect ratio amounting to 10^{-4} (resulting from fitting the Young's moduli of mixes 1-3). The high-density C-S-H gel consists of 30% (volume) gel pores and 70% (volume) solid C-S-H bricks with an aspect ratio amounting to 0.12 [3].

The hydration-induced evolution of the volume fractions of the constituents of cement paste is quantified as a function of w/c and ξ, based on EDF's *Vi(CA)$_2$T* v2 code. Hydration of clinker is simulated through simplified kinetics approaches from Avrami [44] and Fuji,

Kondo [45]. Stoichiometry is enforced through commonly used simplified hydration reactions of clinker components C_3S, C_2S, C_3A, C_4AF. Details regarding the *Vi(CA)$_2$T* v2 code and its hydration module can be found in Refs. [46, 37]. The hydration module yields the evolution of volume fractions of the chemical constituents of cement paste. In order to distinguish between inner and outer hydrates, the Tennis-Jennings model [47] is used. Portlandite and other hydrates are assumed to follow the same inner/outer repartition as C-S-H. As this benchmark application provides the global degree of hydration ξ, the latter is used instead of time to retrieve the amounts of the phases of cement paste from *Vi(CA)$_2$T* hydration simulation results.

C-S-H bricks and platelets are considered to exhibit a deviatoric creep tensor function according to Eq. (12). The creep function (12) is a simplification of the micromechanical model of C-S-H gel creep [4] where creep is assumed to stem from viscous sliding of C-S-H sheets inside bricks. Regarding these bricks, Sanahuja and Dormieux [4] considered a transverse isotropic compliance tensor function (whose creep part is non zero only for shear stresses activating sheets sliding), while in the current model the latter is isotropic (and the creep part is deviatoric). Elastic phase properties are given in Table 2; the Young's modulus of C-S-H bricks and platelets is identified from experimental Young's modulus results on mixes 1-3, while Poisson's ratio is taken as 0.24.

Creep homogenization is performed by the upscaling module of *Vi(CA)$_2$T* [37], using the correspondence principle, see above. Finally, the Laplace-Carson transform is numerically inverted by the Stehfest algorithm [48].

4. The benchmark

The three multiscale models are used to model the viscoelastic properties of cement pastes, mortars, and concretes by means of homogenization of the viscoelastic properties of the material constituents. The material phases are considered to exhibit universal viscoelastic properties, i.e. the elastic and creep behavior at microstructural level neither changes when composition of the material is modified, nor does it change during the hydration. The universality of viscoelastic properties is applicable to hydrates which precipitate at early and mature ages, as long as the hydrates are well-saturated (e.g. by means of water-curing), as demonstrated by previous multiscale modeling at the cement paste scale [10]. Herein this hypothesis is revisited and its verification at mortar and concrete scales is tested. Therefore, the

creep constants at the hydrate scale are first identified by means of top-down identification based on cement paste Mixes 1-3. Thereafter, the short-term macroscopic creep of mortar and concrete Mixes 4-6 as well as the longer-term creep of cement paste Mix 7 is predicted and the model performance is assessed.

4.1. Identification of C-S-H creep behavior

To quantify the creep behavior of C-S-H hydrates, the creep test results of cement paste mixes tested at TUW (Mixes 1-3) are downscaled to the hydrates, as shortly summarized next. The loading in these creep tests is applied at virtually constant stress rate $\dot{\sigma}^* = 2$ MPa/s. After reaching the plateau stress σ^* at time t^*, it is kept constant, yielding a bilinear function for the stress rates as

$$\dot{\sigma} = \begin{cases} \dot{\sigma}^* = \text{const} & \forall t < t^*, \\ 0 & \forall t \geq t^*. \end{cases} \tag{14}$$

Model-predicted macroscopic viscous strains $\varepsilon_v^{\text{mod}}$ read as

$$\varepsilon_v^{\text{mod}}(t) = \int_0^t J_v(t - \tau)\, \dot{\sigma}\, \mathrm{d}\tau, \tag{15}$$

with J_v denoting the viscous part of the 1111-component of the homogenized creep tensor function related to the cement paste scale. As the viscous creep function $J_v(t - \tau)$ is obtained for distinct times, Eq. (15) is integrated numerically by applying the trapezoidal rule.

In order to obtain the creep constants $\mu_{c,h}$ and β_h related to the hydrate creep function (12) employed in the three Models 3N, 4M and 5P, the error between model-predicted creep strains according to Eq. (15) and their experimental counterpart is minimized. In mathematical terms,

$$\sum_{i=1}^{n_{w/c}} \sum_{j=1}^{n_\xi} \sum_{k=1}^{n_t} \left[\varepsilon_v^{\text{mod}}(t_i) - \varepsilon_v^{\text{exp}}(t_i) \right]^2 \to \min . \tag{16}$$

In Eq. (16), the sum over $n_{w/c} = 3$ indicates that three different cement paste mixes exhibiting $w/c \in \{0.42, 0.45, 0.50\}$ are tested, the sum over $n_\xi = 167$ indicates that 167 creep tests were performed on each cement composition for different maturity states, and the sum over $n_t = 20$ indicates that 20 time values $t \in [0, 3 \text{ min}]$ are considered. Solving the minimization problem (16) provides model-specific optimal creep constants reading as

$$\begin{aligned} \text{3N:} \quad & \mu_{c,h} = 20.9 \,\text{GPa}, \quad \beta_h = 0.25, \\ \text{4M:} \quad & \mu_{c,h} = 14.9 \,\text{GPa}, \quad \beta_h = 0.18, \\ \text{5P:} \quad & \mu_{c,h} = 18.1 \,\text{GPa}, \quad \beta_h = 0.24. \end{aligned} \tag{17}$$

Interestingly, the optimum hydrate shear creep modulus for models 3N or 5P is 40% larger than for model 4M. The microstresses in needle- or platelet-shaped hydrates (model 3N or 5P) are, on average, larger than the microstresses in the hydrate matrix (model 4M), leading to larger viscous strains in needle- or platelet-shaped hydrates. In order for the three models to agree with the macroscopically measured creep properties, the needle- or platelet-shaped hydrates themselves need to creep less (higher shear creep modulus) than the hydrate matrix. A comparison of model realizations for hydrate creep constants from Eq. (17) with experimental data is depicted in Fig. 5-7.

Figure 5: Model performance for Mix 1, cement paste $w/c = 0.42$

Figure 6: Model performance for Mix 2, cement paste $w/c = 0.45$

Experimentally determined viscous strains are prone to errors related to imprecise measurements of the elastic modulus due to short-term creep deformations, in particular at early ages. In order to cope with these difficulties, we consider that the elastic modulus from experiments, denoted E^{exp}, is only precise by $\pm 3\%$. This way, we obtain an upper bound $E^{up} = 1.03\, E^{exp}$ and a

Figure 7: Model performance for Mix 3, cement paste $w/c = 0.50$

lower bound $E^{low} = 0.97\, E^{exp}$. By analogy, we obtain upper and lower bounds for the experimental viscous strains $\varepsilon_v^{exp}(t)$ by considering E^{up} and E^{low}, respectively, see the bounds of the gray areas in Figs. 5-10.

4.2. Bridging length scales: from hydrates to mortar and concrete

Herein, we aim to validate the creep models and the identified hydrate creep constants, by comparing experimentally measured and model-predicted viscous strains $\varepsilon_v(t)$ during the minutes-long loading regime for mortar and concrete mixes 4-6. Model predicted strains are obtained by analogy to the procedure described in the previous section. The stress rates $\dot{\sigma}^*$ in the loading regime amount to 2 MPa/s for Mix 4 and 5, while for the VeRCoRs mix 6, applied stress rates increase with the age of the material, see Sec. 2.2.

Model predictions for mixes 4, 5, and 6 are illustrated in Figs. 8-10. Most of the predicted viscous strains (normalized by the plateau stresses σ^*) fall in between the intervals of the experimental data. Many model predictions are parallel to the experimentally measured evolutions. This demonstrates the characteristic accuracy with which macroscopic creep of cement paste, mortar, and concrete can be predicted based on universal C-S-H hydrate creep functions at the microscale.

While the parallelism of predictions and experiments in Figs. 8-10 underlines the performance of creep modeling, a vertical shift between the centerline of the gray experimental area and the predictions can be observed for Mixes 5 and 6, which is discussed next. For Mix 5, model predictions are situated close to the lower bound, referring to $E = 0.97\, E^{exp}$. The performance for this mix can be improved based on consideration of water uptake by the open porosity of the aggregates during material production (= mixing of raw materials),
10

Figure 8: Model performance for Mix 4, mortar $w/c = 0.50$

Figure 9: Model performance for Mix 5, concrete $w/c = 0.50$

Figure 10: Model performance for Mix 6, concrete $w/c = 0.52$

and slow back-suction of water to the cement paste matrix during hydration, such that the effective water-to-cement mass ratio evolves during hydration, see Fig. 8 of [12]. Still, this water migration phenomenon is very slow, so that the effective water-to-cement mass ratio is virtually constant throughout every single three-minutes creep test. As for Mix 6, for which the the

loading/unloading moduli are used as an estimate for the elastic modulus, model predictions agree, in general, very well with the upper bound of the gray area, which corresponds to moduli increased by 3% compared to the experimentally determined loading/unloading moduli. This indicates that the actual elastic moduli might be 3% higher than the loading/unloading moduli. Notably, an underestimation of the elastic modulus does result in *tensile* viscous strains at the very beginning of the loading, manifesting in normalized strains below the abscissa in Fig. 10) for the centerline of the gray area which refers to $E = E^{\text{exp}}$. Avoiding this so-called "tensile undershooting" has been the basis for separating elastic and creep strains for mixes 1-5 [11, 12], and it would result in the experimental interval to shift upwards, such that the centerline comes closer to the model-predicted viscous strains.

As for quantitatively discussing the model performance, temporal evolutions of the creep strain rates, $\dot{\varepsilon}_v(t, t')$, are of interest, where t' denotes the material age at the start of the creep test. Hence, we introduce the mix-specific mean relative errors ϵ as the mean of the absolute value of the difference between modeled creep strain rates and the experimentally measured creep strain rates, normalized by the mean experimental creep strain rate, reading as

$$\epsilon = \frac{1}{n_{\text{age}} n_t} \sum_{j=1}^{n_{\text{age}}} \frac{\sum_{i=1}^{n_t} \left| \dot{\varepsilon}_v^{\text{mod}}(t_i, t'_j) - \dot{\varepsilon}_v^{\text{exp}}(t_i, t'_j) \right|}{\frac{1}{n_t} \sum_{i=1}^{n_t} \dot{\varepsilon}_v^{\text{exp}}(t_i, t'_j)} \quad (18)$$

whereby the creep strain rate evolutions are resolved for $n_t = 200$ time steps within the last two-thirds of the load plateau and for $n_{\text{age}} = 6$ ages as depicted in Figs. 5-10. Notably, experimental creep strain rates were smoothed by means of moving averages coupled with Power-law fits in order to minimize the error related to experimental noise. Rather than model errors based on creep strains, model errors ϵ related to creep strain *rates* according to Eq. (18) are free of the uncertainty related the determination of the elastic modulus and therefore render a trustworthy quantity to assess the model performance.

Table 3: Model errors ϵ according to Eq. (18) in percent

Model	Mix 1	Mix 2	Mix 3	Mix 4	Mix 5	Mix 6	Mean
3N	8.8	8.3	11.9	25.6	6.5	12.2	12.2
4M	25.5	24.4	26.8	22.1	25.2	46.9	28.5
5P	12.2	14.2	25.9	42.4	14.1	19.2	21.4

Comparing the model performance among the three micromechanical models, we remark that representing

the hydrate foam as a porous polycrystal with elongated (Model 3N) or flattened (Model 5P) hydrates rather than as a porous material with a hydrate matrix (Model 4M), reduced the errors ϵ significantly, see Table 3. At material ages above approximately 60h, predicted creep strains of all three models are very close to the experimental data. At very early ages, however, the predicted creep strains of Model 4M on the basis of a C-S-H hydrates matrix are too small. We conclude that hydrate shape does matter for the prediction of creep rates at early age, for which the porosity is still high. The consideration of non-spherical hydration products is a way to enhance the accuracy of creep predictions for early material ages. This is in line with micromechanics-based findings from Sanahuja et al. [49], who emphasized that the shape of solid particles is a first order parameter on effective elasticity when the material's porosity is high. A similar conclusion for micromechanics-based strength and elasticity predictions has been drawn from Pichler et al. [50]. Notably, local anisotropies of C-S-H in terms of C-S-H gel strands have been reported to emerge naturally in statisticial physics-based mesoscale modeling [51]. Moreover, anisotropic stiffnesses of the C-S-H nanoparticles have been found by means of molecular simulations [52], and, have then been used to successfully predict the macroscopic poro-elastic behavior of hydrating cement paste [9], again by means of incorporating non-spherical C-S-H shapes.

4.3. Bridging time scales: from minute-long tests at early-age to days-long test at mature ages

After successful upscaling from micro- or nanometer-sized C-S-H hydrates to centimeter-sized mortar or concrete volume elements, we herein aim time scale bridging, i.e. for model validation based on creep durations which are orders of magnitude longer than the three minutes-long creep tests on Mixes 1-3, for which the hydrate creep properties were determined. In more detail, we aim for predicting the viscoelastic behavior of a mature cement paste tested from Tamtsia and Beaudoin [13]. The material was subjected to 30 days-long loads, which is by more than four orders of magnitude longer than in the three-minutes long creep tests. All three models are therefore evaluated for the tested composition and maturity: a cement paste exhibiting $w/c = 0.50$ and $\xi = 0.87$ [13, 10]. The model-predicted (total) creep functions for models 3N and 5P agree very well with experimental counterpart, see Fig. 11. Predictions of Model 4M slightly overestimate the experimental results, due to the representation of the creeping hydration

Figure 11: Model performance for long-term creep test at mature ages (Mix 7), cement paste $w/c = 0.50$

products as a matrix phase. The good performance underlines that the universal hydrate creep properties are valid for predicting longer-term creep properties of mature pastes. Time scales from minutes-long creep tests at material ages of one to several days were bridged successfully to days-long creep tests at material ages of 30 years.

4.4. Validation of elastic modulus evolutions

While primarily focussing on the comparison of early-age creep strains, we finally compare the early-age evolution of the macroscopic elastic moduli for Mixes 1-6. Model predicted macroscopic elastic moduli E^{mod} are based on intrinsic elastic phase properties given in Table 2 and on the calorimetry-based hydration degrees coupled with the hydration models. Notably, as for Models 4M and 5P, C-S-H hydrate properties have been back-identified from the measured test results of Mixes 1-3, while Model 3N relies on literature values for the hydrate stiffnesses. Experimentally determined elastic moduli E^{exp} are again considered to be accurate by ±3%.

In general, model-predicted evolutions for all six mixes are very close to the experimental results, see Fig. 12. Deviations between model and experiments are typically only a few percent. Interestingly, for mortar Mix 4, measured moduli are consistently higher than the model predictions, while the modulus evolution of the concrete Mixes 5 and 6 are accurately predicted. This could be improved by adjusting sand and aggregate properties. In more detail, the modulus of the sand grains might be slightly underestimated in all models, while the modulus of the aggregates might be overestimated.
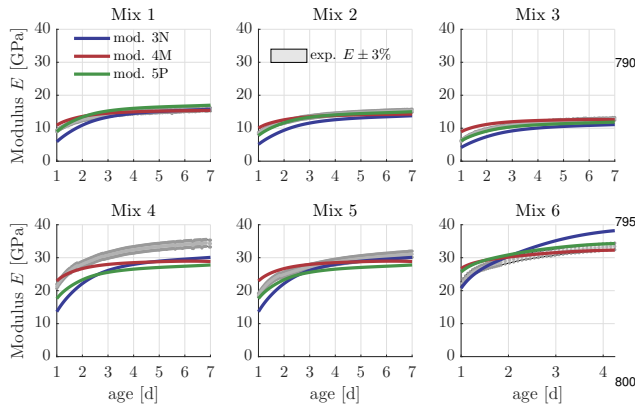

12

Figure 12: Model performance for early-age elastic modulus evolutions based on Mixes 1-6

5. Discussion

Successful length and time scale bridging provides the motivation to discuss the potentials and limitations of the micromechanics-based creep homogenization models. Particular focus is given to the characterization of hydrate creep, the role of the water, and the role of interfacial transition zones between aggregates and the cement paste matrix.

Experimental access to the basic creep properties of hydration products such as C-S-H, the key for modeling macroscopic creep properties of cementitious materials, is still limited. Nanoindentation creep testing [53, 54, 55] has provided some insights on hydrate creep at microscopic length scales. However, the tested half-spaces in nanoindentation tests are loaded heavily and deform thus elasto-plastically, i.e. the hydrates are subjected to stresses even beyond their elastic limit. As such, non-linear creep is likely to occur. Given that our benchmark scope is the prediction of basic creep, i.e. the prediction of macroscopic creep of cementitious materials subjected to stress levels which are smaller than 30 % of the uniaxial compressive strength, basic hydrate creep properties would be required. In this context, Zhang et al. [56] have compared nanoindentation creep tests with macroscopic creep tests and remarked that creep rates differed by one to two orders of magnitude. Only after several months to several years, macroscopic creep moduli were proportional to the contact creep moduli evaluated in minutes-long nanoindenation tests. As experimental techniques for identification of basic creep properties for hydrates have yet to be established, we herein rely on top-down identification based on macroscopic creep tests. This strategy continues the long tradition of identification of physical properties of material constituents which are not (yet) experimentally quantified [5, 57, 10, 58].

Next, the role of water in the porous microstructure is discussed. The models consider constant, intrinsic creep properties of hydrates. This simplification limits the model to experiments with "well-saturated" hydrates. Drying processes change the hydrate creep behavior [13, 59], which is beyond the level of development of the presented models for well-saturated hydrates. Self-desiccation due to the ongoing hydration process might also change the hydrate creep behavior. For the studied pastes with $w/c \geq 0.42$, self-desiccation induced changes of the hydrate creep behavior are disregarded, since internal relative humidities for maturities of up to one week (test age for Mix 1-6) are expected to be larger than 90%, as studied by Lura et al. [60] in a paste with $w/c = 0.37$. Moreover, water migration between the aggregates and the hydrating cement paste, can change the effective water content in the paste, and thus the material's creep behavior. Upon mixing, water might be absorbed by the porous aggregates. Some or all of the absorbed water might then migrate back due to capillary suction, a process typically referred to as internal curing [60, 61, 62]. Herein, such transfer mechanisms are disregarded, but previous micromechanics modeling has shown that the model performance can be improved by incorporating a phenomenological model for back-suction, see [12] for details. Finally, we note that water is considered as liquid phase, thus, the solid stiffness of the all pore phases vanishes. If macroscopic loads activate pore pressures, this is to be accounted for in the context of microporomechanics [9]. Herein, however, it is assumed that capillary pores are partially saturated and connected, such that no significant capillary pore pressures develop.

In all three models, the cement paste or mortar is considered as a homogeneous matrix hosting sand grains and aggregates. Interfacial transition zones (ITZs) around the aggregates with slightly higher porosity [63], slightly lower mechanical properties [64] and therefore typically labelled as weakest links in the microstructure of concrete [65], are not considered explicitly. ITZs are well known to significantly affect the shape of the the stress-strain curve and the strength of concrete [66] due to stress concentrations around the stiff aggregates [67, 68]. As for micromechanics-based elasticity homogenization, however, neglecting the ITZs does not lead to an any significant overestimation of the concrete stiffness [69, 70, 71, 72, 73]. Thus, ITZs are herein disregarded for creep homogenization. Moreover, introduction of ITZs as additional phase in the concrete RVE would require the quantification of age-specific

13

and mix-specific ITZ properties such as thickness and porosity, for which experimental access is still limited.

6. Summary and conclusions

Three micromechanics creep models have been applied in the framework of a modeling-benchmark carried out under the umbrella of the COST Action TU1404. For each one of the used models, the creep activity of microscopic hydration products was quantified by means of downscaling results of macroscopic minutes-long creep tests performed on cement pastes at early material ages. The identified creep properties were considered to be intrinsic parts of the models, i.e. to be independent of the degree of hydration and of the mix proportions used for the production of the cementitious materials. This was the basis for predicting the creep activity of mortars and concretes at early age, as well as of cement paste at mature ages. Model predictions were compared qualitatively and quantitatively with results from experiments which were not involved in the development of the models.

From the results of the benchmark, it is concluded that creep of cement pastes, mortars, and concretes can be traced back to the specific ("intrinsic") creep behavior of microscopic calcium-silicate-hydrates. As far as modeling is concerned, this implies that creep *constants* can be assigned to the hydrates, rather than evolving creep *parameters*. Once these constants are identified, the respective multiscale model can be evaluated for any specific initial composition of interest and any specific maturity of the material.

The prediction quality is related to the essential features of the microstructural representation, including the number of different observation scales, the number of different material phases, the quality of the ellipsoidal shape assigned to the material phases, and the type of envisaged phase interaction. The benchmark study suggests that the consideration of non-spherical shapes for C-S-H hydrates to represent the material's micro-anisotropy in combination with the polycrystalline microstructural representations (self-consistent homogenization scheme) yields a better model performance, as compared to C-S-H hydrates as a matrix (Mori-Tanaka homogenization scheme), in particular for highly porous microstructures as encountered at early material ages. Self-consistent homogenization including non-spherical shapes, however, is more complex to implement. Moreover, additional choices for quantifying the C-S-H phase shapes are required. As for practical applications, a trade-off must be made between the complexity of the model and the corresponding performance. In any case, all of the here-discussed multiscale models are computationally very efficient, i.e. the required computational efforts are by orders of magnitude smaller compared to what nested Finite Element resolutions of the microstructure require.

The study also underscores the importance of separating instantaneous elastic strains from time-dependent creep strains. Because the models distinguish rigorously between these two contributions to the overall deformations, it is essential for the evaluation of experiments that the same level of rigor is applied. Estimating the modulus of elasticity based on a loading modulus, or an unloading modulus, or the average of the two, has an insignificant influence on the numerical value of the modulus of elasticity, but a significant effect on the extracted creep deformation, particularly so in ultra-short creep tests which last for a few minutes only. Thus, it is essential to understand that important creep deformation develops also during short loading or unloading ramps.
